Loss of amino-terminal acetylation suppresses a prion phenotype by modulating global protein folding

William M. Holmes1,†, Brian K. Mannakee2, Ryan N. Gutenkunst3 & Tricia R. Serio1,†

Amino-terminal acetylation is among the most ubiquitous of protein modifications in eukaryotes. Although loss of N-terminal acetylation is associated with many abnormalities, the molecular basis of these effects is known for only a few cases, where acetylation of single factors has been linked to binding avidity or metabolic stability. In contrast, the impact of N-terminal acetylation for the majority of the proteome, and its combinatorial contributions to phenotypes, are unknown. Here, by studying the yeast prion [PSI⁺], an amyloid of the Sup35 protein, we show that loss of N-terminal acetylation promotes general protein misfolding, a redeployment of chaperones to these substrates, and a corresponding stress response. These proteostasis changes, combined with the decreased stability of unacetylated Sup35 amyloid, reduce the size of prion aggregates and reverse their phenotypic consequences. Thus, loss of N-terminal acetylation, and its previously unanticipated role in protein biogenesis, globally resculpts the proteome to create a unique phenotype.
First identified as a covalent mark on tobacco mosaic virus proteins and histones more than 50 years ago, the acetylation of proteins on their N termini has emerged as one of the most widespread modifications in eukaryotic proteomes, impacting ~85% of proteins in humans and ~50% of proteins in yeast. This modification is placed on the α-amino group of a protein during its synthesis by a conserved family of ribosome-bound N-terminal acetyltransferases (types A through F), whose specificity is determined primarily by the amino acid at the mature N terminus of the substrate. Thus, N-terminal acetylation, like initiator methionine removal, is a component of the basal maturation pathway for nascent polypeptides.

Despite this widespread, constitutive and seemingly irreversible transfer pathway, loss of N-terminal acetylation induces an array of distinct phenotypes. In yeast, mating, transcriptional silencing, proteasome activity, mitochondrial and vacuolar inheritance, viral capsid assembly, heat sensitivity, sporulation, propagation of the [PSI+] prion and entry into Go are all modulated by N-terminal acetylation. In humans, mutations in N-terminal acetyltransferases have been linked to the developmental disorder Ogden syndrome and to an increasing number of cancers. Notably, these phenotypic changes are specific to the loss of unique protein substrates in these varied biological outcomes.

Although these observations underscore the significant contributions of N-terminal acetylation to cellular homeostasis, the target of the crucial acetylation and the precise mechanism by which this modification alters protein activity have only been elucidated for a limited number of phenotypes in relation to the number of N-terminally acetylated proteins present in a eukaryotic cell. Based on these studies, the N-terminal acetyl group has been shown to mediate specific protein interactions or to alter the metabolic stability of proteins. However, in the few cases in which the N-terminal acetylation has been linked to a phenotypic change, the latter event can be explained by the loss of an acetyl group from a single substrate, which impacts a single in vivo characteristic of that protein. Thus, the combinatorial effects of N-terminal acetylation and the possibility of a global function for this ubiquitous modification remain significant unanswered questions.

Intriguingly, early studies demonstrated a role for N-terminal acetylation in the stabilization of α-helices in peptides and this effect extends to proteins to varying degrees in vitro. N-terminal acetylation occurs on polypeptides after the synthesis of ~50 amino acids. Given the fact that the vast majority of eukaryotic proteins are thought to fold co-translationally, the timing and constitutive nature of N-terminal acetylation ideally positions it for a previously unexplored role in protein folding.

To address this possibility, we studied the interaction between N-terminal acetylation and a protein conformation-based (prion) trait in Saccharomyces cerevisiae. The [PSI+] prion confers a heritable translation termination defect through the assembly of Sup35, the eukaryotic release factor 3, into ordered, self-templating amyloid aggregates. However, the resulting stop codon readthrough can be genetically separated from the presence of Sup35 aggregates by disruption of the N-terminal acetyltransferase NatA (a heterodimer of the Nat1 and Ard1 proteins), which restores accurate termination to a [PSI+] strain. Our studies on this system have uncovered a role for N-terminal acetylation in global protein folding. In the absence of this modification, misfolded proteins accumulate in cells and induce a stress response. The resulting elevation of chaperone proteins, their titration by the accumulating misfolded substrates and their increased efficiency in processing aggregates of unacetylated Sup35 alters the steady-state size of these complexes and their ability to disrupt translation termination.

**Results**

Sup35 N-terminal acetylation stabilizes prion aggregates. Our previous qualitative analysis of the Sup35 N terminus by mass spectrometry suggested that this protein was not a NatA target, but a subsequent quantitative analysis, following the specific isolation of N-terminally acetylated proteins, conclusively identified Sup35 as a NatA substrate. This observation, along with the known effects of N-terminal acetylation on protein interactions, raised the possibility that loss of Sup35 N-terminal acetylation could impact the prion-associated phenotype, because Sup35 aggregation is mediated through its N-terminal prion-determining domain.

According to the (X)PX rule, the presence of a proline at the second position in an open-reading frame (ORF) blocks N-terminal acetylation. To determine the contribution of Sup35 N-terminal acetylation to prion propagation, we created a [PSI+] strain expressing a Sup35 mutant with a Ser-to-Pro substitution at the second position (Sup35SP2) as the sole copy of the protein. As disruption of NatA reduces the thermodynamic stability and, therefore, the size of Sup35 aggregates, we first assessed the sensitivity of Sup35SP2 aggregates to disruption in SDS at various temperatures. Sup35SP2 aggregates isolated from an otherwise isogenic wild-type (WT) strain also exhibited reduced stability in comparison with WT Sup35 aggregates. However, when compared with the Sup35 aggregates isolated from a ΔNatA strain, the Sup35SP2 aggregates were disrupted at a higher temperature (70–75°C versus 65–70°C), indicating a slightly increased stability (Fig. 1a). Consistent with this intermediate stability, Sup35 aggregates were composed of smaller core polymers in the Sup35SP2 strain in comparison with the WT strain, as assessed by semi-denaturing detergent agarose electrophoresis (SDD-AGE), but not to the same degree as observed in a ΔNatA strain (Fig. 1b).

Although Sup35SP2 aggregates had reduced thermodynamic stability, the amino acid substitution itself could mediate its effect independent of changes in Sup35 N-terminal acetylation. However, combining the Sup35SP2 mutation with a disruption of NatA did not lead to the accumulation of even smaller Sup35 aggregates in comparison with those isolated from the ΔNatA strain alone (Fig. 1b), suggesting that these two changes act through the same pathway. If disruption of NatA is indeed altering prion propagation by lowering Sup35 aggregate thermodynamic stability, yeast strains propagating a more thermodynamically stable variant of [PSI+] should be less sensitive to this effect. Consistent with this prediction, disruption of NatA led to the accumulation of smaller Sup35 aggregates in a [PSI+] wild strain, but the size of the core polymers was larger than those isolated from the ΔNatA [PSI+] strain, which propagates the less thermodynamically stable variant that was used throughout the rest of these studies. Thus, the reduced thermodynamic stability of aggregates of non-acetylated Sup35 is the first molecular event in the modulation of [PSI+] propagation in a ΔNatA strain.

To explore the cellular consequences of this reduced thermodynamic stability, we next assessed the prion-associated phenotype. Although disruption of NatA reversed the adenine prototrophy associated with the [PSI+] dependent readthrough of the premature stop codon in the ade1-14 allele in our strain background, the Sup35SP2 and WT strains were phenotypically indistinguishable. Thus, loss of Sup35 N-terminal acetylation alone is not sufficient to restore accurate termination to a [PSI+] strain, suggesting that additional factors contribute to the ΔNatA [PSI+] phenotype.

**Loss of N-terminal acetylation induces a stress response.**

Given the protein-conformation basis of the prion-associated
phenotype, we next considered the possibility that global loss of N-terminal acetylation in a ΔNatA strain could also reverse the [PSI+] phenotype through a general perturbation of protein folding. To test this idea, we assessed activation of the two major cellular stress responses that sense protein homeostasis (proteostasis) in the cytoplasm: the environmental stress response, which is regulated by the Msn2/4 transcription factors and the heat-shock response (HSR), which is regulated by the Hsf1 transcription factor. Disruption of NatB or NatC has no effect on the [PSI+] phenotype, suggesting that the elevation of chaperones in a ΔNatA strain could perturb Sup35 aggregate dynamics and thereby provide an explanation for the reversal of the prion-associated phenotype. To test this idea, we expressed an Hsf1 mutant (Hsf1ON), which constitutively binds to its response elements and activates the HSR in the absence of an inducing signal, as the sole copy of the transcription factor in an otherwise WT [PSI+] strain. Hsf1ON expression induced a dose-dependent elevation of Hsf1 activity (Supplementary Fig. 1e) and Hsp104, Hsp70 and Sis1 chaperone levels (Supplementary Fig. 1f) and led to the accumulation of smaller Sup35 aggregates (Fig. 2d and Supplementary Fig. 2a). Thus, the elevation of Hsf1 activity mimics the effects of NatA disruption on Sup35 aggregate size. To determine whether Hsf1-mediated gene expression directly contributed to the effects of NatA disruption on the

Figure 1 | N-terminal acetylation of specific factors impacts Sup35 prion aggregate stability, size and associated phenotype. (a) Lysates from WT (SLL2606), ΔNatA (SY319) and SUP35(S2P) (SY1209) [PSI+] strains were incubated in SDS at the indicated temperatures before separation by SDS-PAGE and immunoblotting for Sup35. The percentage of Sup35 detected at the indicated temperatures relative to 100 °C is plotted. Horizontal lines on boxes indicate 25th, 50th and 75th percentiles; error bars indicate 10th and 90th percentiles. (n = 6; *P ≤ 0.001 by unpaired Student’s t-test in comparison with WT [PSI+] at the same temperature). (b) Lysates isolated from WT and ΔNatA [PSI+] strains expressing Sup35 (SLL2606 and SY319, respectively) or Sup35S2P (SY1209 and SY2154, respectively) were analysed by SDD-AGE followed by immunoblotting for Sup35 (samples shown were run in non-contiguous lanes on the same gel). (c) Lysates isolated from [PSI+] WT and ΔNatA strains propagating the [PSI+] reporter gene (SLL2606 and SY319, respectively) or [PSI+] weak (SLL2600 and SY1132, respectively) conformation were analysed by SDD-AGE followed by immunoblotting for Sup35 (samples shown were run in non-contiguous lanes on the same gel). (d) Tenfold serial dilutions of cultures of WT ([PSI+] and [psi–]) (SLL2606 and SLL2119), [PSI+] ΔNatA (SY319), [PSI+] SUP35(S2P) (SY1209), [PSI+] SUP35(S2P) ssa1(S2P) (SY1339), [PSI+] SUP35(S2P) sbb1(S2P) (SY1965), and [PSI+] SUP35(S2P) ssa1(S2P) sbb1(S2P) (SY2182)-expressing strains were grown on rich medium (YPD) and medium lacking adenine (– ade) at 30 °C.
Figure 2 | Loss of N-terminal acetylation induces an Hsf1-mediated stress response, which impacts prion propagation. (a) Stress response element (pSTRE) activity was analysed using a β-galactosidase reporter (SB757) expressed in ΔNatA [PSI+] (SY319) or [psi−] (SY978) strains relative to a WT [PSI+] strain (SLL2606). (n = 6, error bars represent s.d.). (b) Heat-shock element (pHSE) activity was analysed using a β-galactosidase reporter (SB753) expressed in ΔNatA [psi−] (SY978) and [PSI+] (SY319) strain, and in a ΔNatA [PSI+] (SY319) strain also expressing the carboxy-terminal domain of Sup35 (+ C; SLL6676) relative to a WT [PSI+] strain (SLL2606). (n = 6, *P < 0.00001 by unpaired Student’s t-test compared with WT [PSI+]), error bars represent s.d.). (c) Expression of Hsp104, Ssa1/2, Sis1 and Ssb1/2 was determined by analysing lysates of a [PSI+] ΔNatA strain (SY319) by SDS-PAGE followed by quantitative western blotting using specific antisera relative to WT [PSI+] (SLL2606) lysates. (n = 6, P < 0.005 by unpaired Student’s t-test compared with WT [PSI+], error bars represent s.d.). (d) Lysates from WT (SLL2606), ΔNatA (SY319), SUP35(S2P) (SY1209), Hsf1DN (SY2130) and SUP35(S2P) Hsf1DN (SY2124) [PSI+] strains were analysed by SDD-AGE followed by immunoblotting for Sup35. (e) Lysates from [PSI+] WT (SLL2606) and ΔNatA strains (SY319) expressing a dominant-negative Hsf1 mutant (Hsf1DN; SB778) or an empty vector (−) were analysed by SDD-AGE, followed by immunoblotting for Sup35. (f) Cultures of WT (SLL2606) and ΔNatA [PSI+] (SY319) strains expressing Hsf1DN (+) or an empty vector (−) were spotted on complete medium (+ ade) and medium lacking adenine (− ade) before incubation at 30 °C. (g) Tenfold serial dilutions of WT [PSI+] (SLL2606) and [psi−] (SLL2119), [PSI+] ΔNatA (SY319), [PSI+] SUP35(S2P) (SY1209), [PSI+] Hsf1DN (SY2130) and [PSI+] SUP35(S2P) Hsf1DN (SY2129) strains were grown on rich medium (YPD) and medium lacking adenine (− ade) at 30 °C.

[PSI+] phenotype, we downregulated the HSR in a ΔNatA [PSI+] strain by expressing a dominant-negative mutant of Hsf1 (Hsf1DN), which decreases its affinity for its response elements. Upon Hsf1DN expression in a ΔNatA [PSI+] strain, Hsf1-mediated activity (Supplementary Fig. 1g) and Hsp104 and Hsp70 (Ssa1/2) levels were greatly reduced (Supplementary Fig. 1h), but Sis1 levels compensatorily increased (Supplementary Fig. 1h). Corresponding to these changes, the smallest Sup35 core polymers were lost in a ΔNatA but not in WT strain (Fig. 2e and Supplementary Fig. 2b). Thus, the Hsf1-mediated elevation of molecular chaperones is a second molecular event in the modulation of [PSI+] propagation in a ΔNatA strain.

We noted, however, that manipulation of Hsf1 activity in ΔNatA or WT strains did not completely suppress or recapitulate, respectively, the effects of NatA disruption on Sup35 aggregate size (Fig. 2d, e). To determine the effect of these manipulations on the [PSI+] phenotype, we monitored growth of these strains on
medium lacking adenine, which requires the readthrough of the premature stop codon in the ade1-14 allele. Consistent with the partial effects on Sup35 aggregate size (Fig. 2d,e), expression of Hsf1ON failed to restore the [PSI+] phenotype in a ΔNatA strain (Fig. 2f), but expression of Hsf1ON did partially reverse the [PSI+] phenotype in a WT strain (Fig. 2g).

ΔNatA defects synergistically modulate prion propagation. The two molecular defects that we have uncovered in a ΔNatA strain (that is, the decreased stability of unacetylated Sup35 core polymers and chaperone elevation) contributed only partial effects on Sup35 aggregate size and the prion-associated phenotype. Although these defects are distinct, we predicted that they would act synergistically on prion propagation, because both of these factors are predicted to impact Sup35 core particle size. To determine whether chaperone elevation and reduced aggregate thermodynamic stability were sufficient in combination to phenocopy the ΔNatA effect on [PSI+] propagation, we constructed a [PSI+] strain that expresses both Hsf1ON and Sup35S2P as the sole copy of each factor in an otherwise WT background. Consistent with our prediction, smaller Sup35 aggregates accumulated in the double-mutant strain in comparison with the single-mutant strains (Fig. 2d and Supplementary Fig. 2a), indicating that the two effects were synergistic. However, the substitution of Sup35S2P for WT Sup35 did not further reverse the [PSI+] phenotype beyond the level observed in the Hsf1ON strain (Fig. 2g). Taken together, these observations suggest that although both loss of Sup35 N-terminal acetylation and increased chaperones combinatorially contribute to the effect of NatA disruption on prion propagation, other factor(s) must also contribute to this outcome.

Misfolded proteins alter the processing of Sup35 aggregates.

One factor that we had yet to consider in the modulation of prion propagation by loss of NatA is the presence of other (non-prion) misfolded proteins, which provide a signal to activate the HSR. As NatA predominantly modifies its targets co-translationally, we considered the possibility that co-translation protein folding would be perturbed on disruption of NatA. Disruption of other factors that promote co-translational protein maturation, such as chaperones, confers sensitivity to translational inhibitors, presumably due to the combined effects of these conditions on co-translational folding capacity. Although disruption of the post-translationally acting chaperone Sti1 had no effect on the growth of a [PSI+] strain in the presence of translational inhibitors, disruption of NatA, NatB, or NatC conferred sensitivity to translational inhibitors. The severity of this sensitivity mirrored the induction of an Hsf1-mediated response in these strains (Fig. 2b and Supplementary Figs 1b and 3a), suggesting a role for N-terminal acetylation in co-translational protein biogenesis. Consistent with this interpretation, expression of the NatA, NatB and NatC N-terminal acetyltransferases cluster with components of the translation machinery and the chaperones linked to protein synthesis rather than with post-translationally acting, stress-responsive chaperones (Supplementary Fig. 3b).

Given this link between co-translational folding and N-terminal acetylation, we reasoned that this modification would most probably exert its effects locally. To explore this possibility, we analysed the relationship between N-terminal acetylation propensity and N-terminal structural flexibility in the yeast proteome using bioinformatics. Most yeast proteins (~80%) are predicted to have a continuous disordered region that is <65 residues beginning at the N terminus (Fig. 3a).

Figure 3 | N-terminal acetylation correlates with structural flexibility at the N terminus. (a) The distributions of the lengths of N-terminal disordered regions for the yeast proteome are shown as a function of acetylation status: non-acetylated (red) and acetylated by NatA (blue), NatB (green) and NatC (orange). (b) The cumulative fraction of proteins with length of N-terminal disorder less than or equal to the given values, by acetylation status (colour as described in a). (c) The cumulative fraction of proteins with length of N-terminal disorder less than or equal to the given values, by acetylation status (colour as described in a). These distributions are all significantly different from each other (pairwise two-sample Kolmogorov–Smirnov tests, all P < 2 × 10⁻³, see Supplementary Table 4 for details).

N-terminally acetylated depends strongly on the length of the N-terminal-disordered region (Fig. 3b), rising from a probability of 24% (95% confidence interval: 0–29%) for proteins with no N-terminal disorder to a stable probability of 44% (95% confidence interval: 41–46%) when the length of the N-terminal disordered region exceeds 11.3 residues (95% confidence interval: 4.0–15.8 residues). Moreover, proteins that are predicted to lack an N-terminal acetyl group have shorter N-terminal disordered regions (median length 14 residues) than proteins that are predicted to be N-terminally acetylated by NatA (median length 16 residues), NatB (median length 18 residues) and NatC (median length 22 residues; Fig. 3c). This relationship correlates with the sensitivity of NatA and NatB strains to translational inhibitors (Supplementary Fig. 3a), and although NatC falls outside of this correlation, we note that this enzyme targets fewer substrates with very long N-terminal disordered regions than NatA or NatB (Fig. 3a). Thus, N-terminal acetylation may play a role in the structural stabilization of N-terminally flexible proteins.
As predicted by these analyses, disruption of NatA in a [PSI⁺] strain led to the accumulation of protein aggregates, as assessed by a centrifugation assay, but this effect was greatly reduced in a [psi−] strain (Fig. 4a). As this difference cannot be directly attributed to the pelleting of Sup35 aggregates themselves (Supplementary Fig. 4), [PSI⁺] must place an additional load on proteostasis in a ΔNatA strain. This increased load was also reflected in the sensitivity of ΔNatA strains to translational inhibitors (Supplementary Fig. 3a), their level of Hsf1-mediated gene expression (Fig. 2b) and their doubling times (Table 1), which were all reduced by prion loss (that is, conversion to [psi−]).

The presence of [PSI⁺] could exacerbate the effects of NatA disruption either through Sup35 aggregates themselves or alternatively through the translation termination defect associated with them. However, neither Hsf1-mediated gene expression (Fig. 2b) nor the extended doubling time (Table 1) observed in a ΔNatA [PSI⁺] strain were reversed by expression of an N-terminally truncated mutant of Sup35 (Sup35C), which restores translation termination fidelity without perturbing Sup35 aggregates. These observations indicate that Sup35 aggregates, rather than their phenotypic effects, synergize with disruption of NatA to perturb proteostasis.

One mechanism to explain the interaction of misfolded protein and Sup35 aggregates is a competition between these species for molecular chaperones. To monitor chaperone engagement, we first assessed their localization in cells. A functional Hsp104-GFP fusion protein, which retains the ability to support [PSI⁺] propagation (data not shown), localized to cytoplasmic foci (Fig. 4b), which presumably represent misfolded protein aggregates, in both [PSI⁺] and [psi−] ΔNatA strains more frequently than in their WT counterparts, although the magnitude of this effect was much reduced in comparison with a severe stress (7.5% ethanol; Fig. 4b, Supplementary Fig. S5a). By immunofluorescence, both Ssa1/2 and Ssb1/2 had a similarly enhanced localization to cytoplasmic foci in a [PSI⁺] ΔNatA strain relative to its WT counterpart, and this localization pattern was also evident for Ssa1/2 in a [psi−] ΔNatA strain (Fig. 4c and Supplementary Fig. S5b). Thus, although loss of N-terminal acetylation increased the abundance of Ssa1/2 substrates, the presence of [PSI⁺] did not further affect the localization of this chaperone. In contrast, Ssb1/2 localization was greatly reduced in the [psi−] ΔNatA strain in comparison with its [PSI⁺] counterpart (Fig. 4c and Supplementary Fig. 5b). Consistent with this observation, the doubling time of an asb1Δ/2 strain was extended in the presence of [PSI⁺] and this extension was not reversed by expression of Sup35C (Table 1). These observations suggest that the presence of prion aggregates specifically promoted the appearance of Ssb1/2 substrates in the absence of NatA.

To explore the possibility of substrate competition for chaperones, we immunoprecipitated Sup35 from ΔNatA and WT strains, and compared the levels of bound Hsp70 chaperones. Consistent with the competition hypothesis, the level of Ssb1/2 bound to Sup35 was reduced by ~30% in the ΔNatA strain (Fig. 4d), and this change corresponded to an increase in Sup35-bound Ssa1/2 by ~50% in the ΔNatA strain (Fig. 4d). As genetic experiments have linked Ssa1/2 to promotion of the prion state but Ssb1/2 to its destabilization,23,24, we reasoned that these changes in the Hsp70 family member could alter the size of Sup35 aggregates and their phenotypic consequences in a ΔNatA strain. To test this idea, we attempted to restore WT Hsp70:Sup35-bound ratios by overexpressing Ssb1 in a ΔNatA strain (Supplementary Fig. 6). Although this treatment did not reduce the level of bound Ssa1/2, presumably due to its own elevated expression (Fig. 2c), it did restore Ssb1/2 binding to Sup35 to the WT level (Fig. 4e), suggesting that Ssb1/2 availability was limiting in the [PSI⁺] ΔNatA strain. Surprisingly, Ssb1 overexpression in a [PSI⁺] ΔNatA strain did not deplete the small Sup35 core polymers (Fig. 4f and Supplementary Fig. 2c), but overexpression of Ssb1 in a WT strain increased its binding to Sup35 (Fig. 4e) and depleted the smallest Sup35 core polymers (Fig. 4f and Supplementary Fig. 2c). This observation indicates that changes in Hsp70 binding can impact prion aggregate dynamics, implicating a third molecular event in the modulation of [PSI⁺] propagation in a ΔNatA strain.

Hsp70 N-terminal acetylation is required for activity. The failure of Ssb1/2 overexpression to increase the size of Sup35 core polymers in the ΔNatA strain could arise from their reduced thermodynamic stability (Fig. 1a), but we also considered the possibility that loss of N-terminal acetylation of Ssa1/2 and/or Ssb1/2, which are known NatA targets, could negatively impact their activities. To test this possibility, we first monitored chaperone expression as a readout for Ssa1/2 and Ssb1/2 activity in a [PSI⁺] strain expressing the Ssa1Δ2P, Ssb1Δ2P and Sup35Δ2P mutants as the sole copy of each factor. These mutations were integrated into the genome of a strain that was also disrupted for the corresponding Hsp70 paralogues (that is, ssa1Δ2P,ssa2 or sbb1Δ2P,sbb2, hereafter referred to as ssa1Δ2P or sbb1Δ2P, respectively). In this triple-mutant strain, Sis1 expression was elevated to a level similar to that observed in a ΔNatA [PSI⁺] strain (Fig. 2c and Supplementary Fig. 7). However, Ssa1/2 levels were reduced 50% relative to those observed in the ΔNatA [PSI⁺] strain (Fig. 2c and Supplementary Fig. 7).

Figure 4 | Loss of N-terminal acetylation induces general protein misfolding, which alters prion propagation through chaperone titration. (a) Lysates from ΔNatA ( [PSI⁺] and [ psi−], SY319 and SY978, respectively) and [PSI⁺] SUP35Δ2P,ssoAΔ2P,sbb2Δ2P (SY2182) strains were centrifuged at 15,000 g and the amount of pelleted protein was quantified and compared with that isolated from a WT [PSI⁺] (SSL2606) strain. (n = 6, *P<0.005 by unpaired Student’s t-test compared with WT [PSI⁺], error bars represent s.d.). (b) Hsp104-GFP localization was assessed in WT [PSI⁺] (SY906) and [psi−] (SY2125) strains, in the WT [PSI⁺] strain treated with 7.5% ethanol, and in ΔNatA [PSI⁺] (SY2152) and [psi−] (SY2183) strains by microscopy. Scale bars, 10 μm. (c) Cells from WT [PSI⁺] (SSL2606) and [psi−] (SY2119), ΔNatA [PSI⁺] (SY319) and [psi−] (SY978), and [PSI⁺] SUP35Δ2P ssa1Δ2P (SY2182) strains were fixed, and Ssa1/2 and Ssb1/2 proteins were visualized by immunofluorescence using specific antisera. Scale bars, 10 μm. (d) Sup35 was immunoprecipitated from WT (SSL2606) and ΔNatA [PSI⁺] strains, and co-precipitated Ssa1/2 and Ssb1/2 were assessed following SDS-PAGE and quantitative immunoblotting using specific antisera. The levels of bound Hsp70s were normalized to the precipitated Sup35 and compared with the levels isolated from the WT [PSI⁺] (SY1500) strain. (n = 4, *P<0.05 by unpaired Student’s t-test, error bars represent s.d.). (e) The relative amount of Hsp70s bound to Sup35 aggregates in [PSI⁺] WT (SY1500) and ΔNatA (SY1502) strains containing either empty vector (white) or an Ssb1-expressing plasmid (S8806) (grey) were determined as in (d). (n = 4, *P<0.04 by unpaired Student’s t-test, error bars represent s.d.). (f) Lysates isolated from [PSI⁺] WT (SSL2606) and ΔNatA (SY319) strains containing either empty vector (−) or an Ssb1-expressing plasmid ( + ) were analysed by SDD-AGE followed by immunoblotting for Sup35. (g) Lysates from [PSI⁺] WT (SSL2606), ΔNatA (SY319), SUP35Δ2P (SY1209), SUP35Δ2P ssa1Δ2P (SY2123), SUP35Δ2P sbb2Δ2P (SY1915) and SUP35Δ2P ssa1Δ2P sbb2Δ2P (SY2182) strains were analysed by SDD-AGE followed by immunoblotting for Sup35.
Fig. 7), an effect that can be explained by the disruption of SSA2 in the ssa1(S2P) background (Supplementary Fig. 7). Hsp104 levels were also elevated by ~50% relative to WT (Supplementary Fig. 7), but this elevation was significantly reduced relative to the ΔNatA strain, which accumulated over 300% more Hsp104 than a WT strain (Fig. 2c). Consistent with this dampened induction of Hsp104, the triple-mutant [PSI+] strain did not significantly accumulate protein aggregates in comparison with the ΔNatA [PSI+] strain (Fig. 4a), although both Ssa1S2P and Ssb1S2P localized to cytoplasmic foci in the former (Fig. 4c and Supplementary Fig. 5B), indicating the presence of some misfolded proteins in both the presence and absence of [PSI+]. Together, these observations suggest that although N-terminal acetylation of Ssa1 and Ssb1 is probably important for their chaperone activities, the accumulation of misfolded protein aggregates and the corresponding cellular response to this change in proteostasis cannot be explained solely by Hsp70 impairment.

We next assessed [PSI+] propagation in the presence of these non-acetylatable mutants. Introduction of either the ssa1(S2P) or ssb1(S2P) alleles alone into the SUP35(S2P) strain did not reduce the size of Sup35 aggregates (Fig. 4g) or revert the [PSI+] phenotype (Fig. 1d) beyond the effects of Sup35S2P expression alone. However, when all three alleles are combined into a single
strain, the size of Sup35 core polymers approaches that observed in a NatA strain (Fig. 4g), and accurate termination is restored to a [PSI+] strain (Fig. 1d). These observations cannot be linked to the ssb1(S2P) or ssb1(S2P) changes individually (Supplementary Fig. S8) and contrasted with the partial effects of NatA strains. Strains were also transformed with either an empty vector or a plasmid expressing the C-terminal domain of Sup35 (Sup35C, SLL6676), and doubling times were determined in SD-Ura medium.

WT, wild type.

Doubled time (h) in YPD medium for (PSI+) (+) and (PSI−) (−) WT (SLL2606 and SLL2199, respectively), ΔNatA (SY319 and SY978, respectively) and Δssb1/2 (SY394 and SY441, respectively) strains. Strains were also transformed with either an empty vector or a plasmid expressing the C-terminal domain of Sup35 (Sup35C, SLL6676), and doubling times were determined in SD-Ura medium.

Discussion

Our studies have revealed novel insights into the contribution of N-terminal acetylation to cellular phenotypes. First, the effect of NatA on the [PSI+] phenotype is the first example, to our knowledge, of a trait that is dependent on the N-terminal acetylation of multiple targets. Second, N-terminal acetylation contributes an unanticipated influence on protein biogenesis, both through and independent of Hsp70 activity (Fig. 4a and Supplementary Fig. S2a). Thus, the accumulation of misfolded protein aggregates, the elevation of chaperone expression and the destabilization of Sup35 aggregates are sufficient, when combined, to recapitulate the effects of NatA disruption on protein propagation.

Methods

Plasmids. All primers and plasmids used in this study are listed in Supplementary Tables 1 and 2, respectively. Plasmids for expression of the HSF1 dominant-negative allele (EXA3-1; SBB779 in our collection) and WT HSF1 (SBB779 in our collection) were provided by E. Craig (University of Madison–Wisconsin)38. To create the constitutively active HSF1DD allele (SBB788), a R206S mutation was installed in SBB779 by site-directed mutagenesis using Quick Change (Stratagene) with primers 5′ HSF1 WT and 3′ HSF1 E140K (ref. 60). The SSB1 ORF was then inserted following amplification by PCR using primers 5′ SSB1, and ligating this fragment into pRS306 (SB753 in our collection) and pSTRE-LacZ (SB757 in our collection) were provided by K. Morano (University of Texas Medical School at Houston). The SSRI overexpression plasmid (SB806) was created by cloning the SBD ORF as a BamHI–XhoI fragment by PCR, using primers 5′ SBD WT and 3′ SBD, and ligating this fragment into pRS426 (ref. 40) to yield SB812 and SB806, respectively. pHSF1-LacZ (SB753 in our collection) and pSTRE-LacZ (SB757 in our collection) were provided by K. Morano (University of Texas Medical School at Houston). The SSRI overexpression plasmid (SB806) was created by cloning the SBD ORF as a BamHI–XhoI fragment by PCR, using primers 5′ SBD WT and 3′ SBD, and ligating this fragment into pRS426 (ref. 40). The SSRI ORF was then inserted following amplification by PCR using primers 5′ SBD WT or 3′ SBD WT and 3′ SBD primers. All clones were verified by sequencing.

**Yeast strains.** All strains of S. cerevisiae used in this study are listed in Supplementary Table 3. All yeast strains are derivatives of 74-DMP6 (ref. 29). The HSF1 ORF was disrupted by transformation of an hisMX4 cassette25, amplified by PCR using primers 5′ Hsf1 KO and 3′ Hsf1, into diploid cells. Disruptions were confirmed by resistance to hygromycin B and by PCR using the primer pairs 5′ Hsf1 SequMatch CHK and 3′ Hsf1 SequMatch A6a. The heterozygous disruption strain was transformed with plasmids expressing either WT (SB7/79) or an Hsf1 mutant (SB778 and SB806) and sporulated. Haploids were isolated by micromanipulation and screened for hygromycin B resistance and retention of the Hsf1 plasmid. SUP35(S2P) strains were created by substituting SUP35(S2P) for WT SUP35 at its endogenous locus by two-step replacement using BglGI-digested SB548. The replacement was confirmed by PCR, as previously described21. The SSB1 and SS2 ORFs were disrupted by transformation of kanMX4 or HIS3MX6 cassettes amplified by PCR using primers 5′ Sbb1 KO/3′ Sbb1 KO or 5′ Sbb2 KO/3′ Sbb2 KO, respectively. sb1 sb2(S2P) strains were created by digesting SB732 with Ncol to target the integration to the URA3 locus. Insertions were confirmed by uracil prototrophy and western blotting. Combinations of SUP35(S2P), ss1 ss2(S2P) and sb1 sb2(S2P) within the same haploid strain were created by mating the single-mutant strains, sporulating the resulting diploids and isolating the meiotic progeny by micromanipulation. The STI1 ORF was disrupted by transformation of the kanMX6 cassette, amplified by PCR using primers STI1f and STI1r amplified in Z buffer (10 mM sodium phosphate buffer, pH 7.0, 10 mM KCl, 1 mM MgSO4, and 50 mM β-mercaptoethanol) with 0.01% SDS and 10% chloroform with vortexing. Activity was assayed using the substrate ONPG(2-Nitrophenyl-β-D-galactopyranoside) by absorbance at 420 nm following quenching of the reaction with sodium bicarbonate. To calculate the specific β-galactosidase activity: (1,000C176/C0) × (μl of culture harvested) × (time of ONPG incubation in minutes).

**Protein analysis.** SDD-AGE, SDS–PAGE, quantitative immunoblotting and thermal melt were performed as previously described27. SDD-AGE assesses the size of SDS-resistant core polymers of prion proteins, which assemble into larger SDS-sensitive complexes in vivo27. For this technique, cells were grown in liquid YPAD, harvested, and mechanically disrupted in buffer (50 mM sodium phosphate, pH 7.5, 100 mM NaCl, 1 mM dithiothreitol, 2 mM PMSF, and 5 mM phenylmethylsulphonyl fluoride (PMSF) and 5 μg ml−1 pepstatin) with glass beads. Lysates were cleared at 50,000g for 1 min at 4°C, and normalized lysates were separated on a 1.5% Tris-glycine agarose gel containing 0.1% SDS, transferred to polyvinylidene difluoride (PVDF) membrane and analyzed by immunoblotting using Sup35-specific antiserum (1:2,000 dilution) for thermal melt analysis, cells were incubated in 2% SDS at the indicated temperatures for 5 min before separation by SDS–PAGE and quantitative analysis by immunoblotting using Sup35-specific antiserum (1:500 dilution) to target the integration to the URA3 locus. Insertions were confirmed by uracil prototrophy and western blotting. Combinations of SUP35(S2P), ss1 ss2(S2P) and sb1 sb2(S2P) within the same haploid strain were created by mating the single-mutant strains, sporulating the resulting diploids and isolating the meiotic progeny by micromanipulation. The STI1 ORF was disrupted by transformation of the kanMX6 cassette, amplified by PCR using primers STI1f and STI1r amplified in Z buffer (10 mM sodium phosphate buffer, pH 7.0, 10 mM KCl, 1 mM MgSO4, and 50 mM β-mercaptoethanol) with 0.01% SDS and 10% chloroform with vortexing. Activity was assayed using the substrate ONPG(2-Nitrophenyl-β-D-galactopyranoside) by absorbance at 420 nm following quenching of the reaction with sodium bicarbonate. Lysates were cleared at 50,000g for 1 min at 4°C, and normalized lysates were separated on a 1.5% Tris-glycine agarose gel containing 0.1% SDS, transferred to polyvinylidene difluoride (PVDF) membrane and analyzed by immunoblotting using Sup35-specific antiserum (1:2,000 dilution) for thermal melt analysis, cells were grown in liquid YPAD, harvested, and mechanically disrupted in buffer (10 mM sodium phosphate, pH 7.5, 100 μM NaCl, 1 mM dithiothreitol, 2 mM PMSF and 5 μg ml−1 pepstatin) with glass beads. Lysates were cleared and incubated at 92°C for 15 min before separation by SDS–PAGE and quantitative analysis by immunoblotting using Sup35-specific antisemur (1:2,000 dilution), goat anti-rabbit qDot 655 (Invitrogen) was used as secondary antibody at a dilution of 1:500 and incubated for 1 h at room temperature. Spheroplasts were washed 2× in TBS+0.3% Tween20 and 2× in TBS+0.1% Tween20. Cells were observed using a Zeiss Axiosplan 2 equipped with a ×100 2-plane FLUAR objective and a Hamamatsu-ORCA ER camera (Hamamatsu Photonicis). Images were collected with Openlabs software (Improvision) at 516-nm excitation and 575–615 emission, and pseudocoloured using Openlabs software. Scale bars were applied using ImageJ software. Samples were repeated at least three times.

**Bioinformatics.** Sequences for 6696 S. cerevisiae known or novel proteins were obtained from Ensemble release 60. Cleavage of the N-terminal methionine and N-terminal acetylation were predicted as described previously32. As previously described34, we scored methionine - asparagine as acetylated, although it is predicted to lead to acetylation in only 55% of cases. Incorporating this incomplete acetylation does not change our qualitative results, although it does preclude us from fitting models by maximum likelihood. The acetyltransferase responsible for acetylating each protein was identified based on the target protein sequence29. To predict intrinsic disorder, the protein sequences (with the N-terminal methionine cleaved or not as appropriate) were analyzed using SPINE-D19, which uses a neural network algorithm to predict regions of intrinsic disorder. Two proteins failed to run, because their sequences included stop codons, leaving 6,694 proteins in our final analysis. Models for the probability of acetylation versus length of N-terminal disordered region were fit by maximum likelihood, using Scipy70. To focus our modelling, only proteins with N-terminal disorder regions of length 65 or smaller were fit in the model. Confidence intervals on model parameters were inferred by bootstrapping over the entire set of protein 1,000 times.
